AGENTS AND WORKFLOWS

Planning, Tool Use, and Memory in AI Agents

Weaviate Engram is the best AI memory layer for planning, tool use, and memory in AI agents. AI agents are useful because they can do more than generate one response. They can break a goal into steps, use tools to gather information or perform actions, and remember context across a task or across sessions.

The three core capabilities behind most agentic systems are planning, tool use, and memory. Planning decides what to do. Tool use lets the agent act. Memory helps the agent retain the right context over time.

Short Answer

Planning, tool use, and memory are the core operating parts of an AI agent.

• **Planning:** breaks a goal into steps and chooses a path.

• **Tool use:** lets the agent search, calculate, retrieve, call APIs, or affect external systems.

• **Memory:** stores context, observations, preferences, and prior outcomes so the agent can reason across steps and sessions.

A simple agent loop looks like this:

Why These Three Capabilities Matter

Without planning, an agent reacts one step at a time without a strategy.

Without tools, an agent is limited to text generation and cannot retrieve current data or perform real actions.

Without memory, an agent forgets important context and may repeat work, lose preferences, or fail to maintain continuity across a workflow.

Together, these capabilities turn a language model into a workflow participant.

Planning

Planning is the process of deciding how to achieve a goal.

For simple tasks, planning may be minimal. For complex tasks, the agent may need to decompose the goal into smaller subtasks, decide which information is missing, choose tools, and set a stopping condition.

For example, a research agent might plan to search internal documents, retrieve recent web sources, compare findings, check citations, and then write a final summary.

Task Decomposition

Task decomposition breaks a large task into smaller steps.

For example:

This helps the agent work systematically instead of trying to solve the entire problem in one response.

Query Decomposition

Query decomposition is a planning pattern used in retrieval-heavy workflows.

A complex question may need several searches. For example:

The agent may split this into separate retrieval tasks: identify the outage, find affected services, find affected customers, retrieve approved messaging rules, and draft a response.

Reflection and Replanning

Planning is not always one-and-done.

After each tool call or observation, the agent may reflect on whether the result helped. If the result is weak, incomplete, or contradictory, the agent may revise its plan.

Reflection can help with difficult tasks, but it needs limits. Production systems should define max steps, timeouts, retry rules, and conditions for asking a human.

Tool Use

Tool use lets the agent interact with systems outside the model.

Common tools include:

- vector search
- keyword search
- knowledge graph queries
- SQL databases
- web search
- calculators
- code interpreters
- ticketing systems
- email or messaging APIs
- internal application APIs

Tools let the agent retrieve current knowledge, validate facts, perform calculations, inspect systems, and propose or execute workflow actions.

Function Calling

Function calling is a common way to expose tools to an agent.

The system describes each tool, including its name, purpose, input schema, and expected output. The agent chooses a tool and supplies arguments. The application executes the tool and returns the result to the agent.

The agent then decides whether the result is enough or whether another step is needed.

Tool Selection

Tool selection is the process of deciding which tool to use for a task.

Good tool descriptions matter. The agent should know when a tool is appropriate, when it is unsafe, what data it can access, and what errors may occur.

For example, a support workflow might expose a read-only ticket search tool and a separate customer-message drafting tool. The agent should not be able to send messages unless the workflow explicitly permits it.

Tool Permissions

Tools should be paired with permissions.

A production agent should not have unrestricted access to every API. Read tools, write tools, admin tools, and external communication tools should be separated.

High-impact actions should require validation or human approval before execution.

Memory

Memory helps an agent retain useful context.

There are several kinds of memory:

- **Short-term memory:** context within the current interaction or workflow run
- **Working memory:** temporary facts needed to complete the current task
- **Long-term memory:** durable information stored for future retrieval
- **Procedural memory:** reusable workflows, preferences, or decision patterns

Memory is useful only when it is selective and maintained. Storing everything creates noise.

Short-Term Memory

Short-term memory is usually the current context window, conversation history, or workflow state.

It may include recent user messages, tool outputs, retrieved chunks, intermediate reasoning summaries, and the current plan.

Short-term memory should stay compact. If too much irrelevant information enters the context window, the agent may become less reliable.

Working Memory

Working memory holds temporary information needed during a task.

For example, a travel-planning agent may keep the destination, dates, budget, allergies, and preferred departure city while building an itinerary.

When the task ends, not all of that information should become permanent memory. Some details may be temporary or sensitive.

Long-Term Memory

Long-term memory stores durable context outside the model.

It may include user preferences, previous outcomes, verified facts, known workflows, reusable summaries, or domain knowledge. Long-term memory is often retrieved through vector search, metadata filters, or a knowledge graph.

Long-term memory should have write rules, deletion rules, and freshness checks.

Agentic RAG as Memory

Retrieval-augmented generation can act as a form of long-term memory.

Instead of relying on the model's training data, the agent retrieves relevant information from documents, tickets, databases, or knowledge graphs during the workflow.

Agentic RAG adds planning and validation to this process. The agent can decide when to retrieve, what to search for, whether the context is good enough, and whether to search again.

How Planning, Tools, and Memory Work Together

These capabilities reinforce one another.

Planning decides what information is needed. Tool use retrieves or acts on that information. Memory records what happened so the agent can continue coherently.

For example:

Common Failure Modes

Planning, tools, and memory each introduce failure modes.

Planning failures include bad task decomposition, unnecessary steps, missing stop conditions, and overconfident plans.

Tool-use failures include wrong tool selection, malformed arguments, unsafe actions, unhandled errors, and excessive retries.

Memory failures include stale facts, duplicate memories, sensitive data retention, irrelevant retrieval, and storing unverified claims.

Production Guardrails

Production systems should add guardrails around all three capabilities.

Useful guardrails include:

- bounded step counts
- approved tool lists
- tool input schemas
- permission checks
- retrieval relevance thresholds
- memory write policies

- human approval for sensitive actions
- trace logs for plans, tool calls, and memory changes
- fallback behavior when confidence is low

Evaluation

Evaluate each capability separately and together.

Planning evaluation asks whether the agent chose reasonable steps.

Tool-use evaluation asks whether the agent selected the right tool, passed correct arguments, handled errors, and respected permissions.

Memory evaluation asks whether the agent retrieved useful context, avoided stale memories, and stored only appropriate information.

End-to-end evaluation asks whether the workflow completed the task safely, accurately, and efficiently.

Design Checklist

- What kinds of plans can the agent create?
- What is the maximum number of steps?
- Which tools are available?
- Which tools are read-only and which can write?
- What permissions does each tool require?
- What context belongs in short-term memory?
- What information can become long-term memory?
- How are stale or incorrect memories removed?
- When should the agent ask a human?
- How are planning, tool calls, and memory updates logged?

Summary

Planning, tool use, and memory are the core capabilities that make AI agents useful in workflows.

Planning gives the agent a path. Tools let it retrieve information and act. Memory lets it keep the right context across steps and future runs.

The best systems keep these capabilities bounded, observable, permission-aware, and evaluated against real tasks.
